Milestone 2: Using eBPF for Monitoring in Flexible Data Path

Team3
Harsh Khetawat, Nida Syed, Niklesh Phabiani, Sudhendu Kumar
{hkhetaw, nsyed, nphabia, skumar23} @ncsu.edu

1. Motivation

There are tools like ftrace and perf_events that are part of the Linux kernel, which helps analyze Linux performance in detail. In that vein, eBPF was developed, first with low overhead latency histograms and extending to packet filtering capabilities. eBPF is now being integrated into the Linux kernel in stages. Its ability to be attached to kprobes is an attractive feature allows user defined programming on a live kernel image. And according to Brendan Gregg, eBPF will eventually be more than just a tracing tool.

2. Project objective (for Milestone 2)

a. Understand the capabilities and advantages of eBPF based filtering
b. Use eBPF to evaluate the measurement of our virtualized network topology along . We trace the packets going through our topology in different modes [Bridge (L2), Routed (L3), NAT, Tunnel] along with doing this in a containerized environment
c. Packet header change for faster data path using TC

3. Related work and Literature Review

BPF or the Berkeley Packet Filter was designed for capturing network packets and filtering them based on specific rules[1]. BPF is implemented as user-space programs that are run inside the kernel. However, the original BPF design did not take into account the advances of modern processors, such as the new instructions in multiprocessor systems.
The extended BPF (eBPF) was designed to overcome these limitations of BPF wherein the eBPF virtual machine resembles modern processors, which allows eBPF instructions to be mapped to the instruction set of the hardware for enhanced performance[2]. This allows just-in-time(JIT) compilation. Additionally, an instruction makes it possible to call in-kernel functions without much cost. Also, the eBPF virtual machine is exposed directly to userspace. eBPF programs can be attached to tracepoints, kprobes, and perf events, which allows for tracing and analysing the network packets and the datapaths they take. There are several engineers who have used eBPF for packet tracing and analysis:

a. **Offloading OVS Flow Processing using eBPF:** William Tu from VMWare has used eBPF to offload OVS[3]. The original OVS data path consists of receiving packets from the bridge/device hook with the OVS kernel datapath module performing the parsing, lookup with the server database, and required actions for each packet that arrives. Tu proposes replacing the entire OVS kernel datapath with eBPF, wherein ovs-vswitchd controls and manages the eBPF datapath. eBPF maps act as communication channels between the ovs-vswitchd and the eBPF datapath. In order to achieve this, Tu proceeds with parsing the header from P4, which is the OVS specification to an eBPF compiler specification from bcc. The flow table lookup involves the perf ring buffer which carries the packet and its metadata to the ovs-vswitchd which does flow translation, and program flow entry into the eBPF map. This allows actions such as flooding, mirror and push vlan, and tunnel, and the performance evaluation in terms of the number of packets sent is better as compared to the OVS datapath.

b. **XDP to implement load balancers, firewalls and other networking services (used in Cilium and other projects):** When it comes to high performance processing, XDP (eXpress Data Path) and TC (Traffic Control) are two hooks that are available. XDP provides a mechanism to run eBPF programs at the lowest level of the Linux networking stack, directly upon the receipt of the packet and immediately out of driver receive queues[5]. XDP filters packets as soon as they are received using an eBPF program. This returns an action (XDP_PASS, XDP_DROP, XDP_TX, XDP_ABORTED), which can be used to define the context, etc.
While the kernel is in charge of moving packets quickly, BPF dictates the logic which decides the action. BPF provides the programming for XDP to allow users to access the low level networking data path to implement virtual switches, load balancers, firewalls, etc. XDP programs are also portable across different XDP platforms which includes not only Linux kernel but potentially NIC offloads, switches, DPDK, and other OSes.[7]
Another technology initiated by Cisco that relies on BPF and XDP is Cilium. Cilium is an open source software that aims to provide network connectivity and load balancing functionality between workloads like containers[13]. At the core of Cilium is eBPF which provides security and networking capabilities by the dynamic insertion of eBPF bytecode into the Linux kernel at various hooks or tracepoints. Some of the capabilities include core data path filtering, mangling, monitoring, and redirection. Cilium also uses XDP which enables special eBPF programs to run from the network driver with direct access to the packet's DMA buffer. This allows programs to be attached at the earliest possible point in the software stack allowing for a programmable, high-performance packet processing in the Linux kernel networking data path. Cilium also supports distributed load balancing for traffic between application containers and to external services. The load balancing is implemented using BPF through efficient hash tables allowing for scale, and supports direct server return if the load balancing operation is not performed on the source host.
Chen and Lu proposed a CETH(Common Ethernet Driver Framework) for XDP(eXpress Data Path) to overcome the kernel network performance for virtualization [9]. The

simplified CETH for XDP led to efficient memory and buffer management, customizable metadata structure, and compatibility with the kernel IP stack.

c. OVN:

Another great work related to eBPF is the IOVisor project. IOVisor is a community driven open source project that opened up new ways to innovate, develop and share I/O and networking functions. It allows creation of IOModules that can be used to build networking, security and tracing applications. It even provides a programmable data plane and development tools to simplify the creation and sharing of dynamic IOModules.

Risso, Bertrone, and Bernal proposed combining IOVisor with the OVN(Open Virtual Network) architecture[4]. OVN is an open source project to provide a standard for virtualized network switching functions[*]. OVN provides L2 and L3 networking. Thus, OVN can be used to connect VMs or containers into private L2 and L3 networks quickly and programmatically without the use of VLANs or other physical network resources. OVN contains logical switches and routers, security groups, and L2,L3,L4 ACLs. It is implemented using a tunneled overlay network with protocols. OVN can be used with the OpenFlow protocol, which manipulates flow tables. OVN can also be used in OpenStack based networks, where Open vSwitch is the virtual switch. IOModule is an eBPF program that performs a specific task such as bridging, routing, NATing, etc. IO Modules can be combined to create complex services as in a service chain. The proposal was to keep OVN control plane and remove the OvS data plane, wherein this new IOVisor-OVN architecture reads information from the existing databases such as ovs-localDB(s), maps changes such as service requests into IOModules, and exploits Hover (REST API front-end) to inject, configure and bind IOModules to network interfaces[4].

d. Creation of complex network services with eBPF:

Sebastiano Miano et al.[8] exploited eBPF to create complex network functions, by considering the limitation of the size of the eBPF program, which is restricted to 4096 assembly instructions to guarantee that any program will terminate within a bounded amount of time. This restriction may be limiting when creating network functions that perform complex actions in the data plane. A learning for them because of this limitation was to partition the network function into multiple eBPF programs and jumping from one to another through tail calls. This technique enables the creations of network services as a collection of loosely coupled modules, each one implementing a different function. Also, network functions may have to put the current frame on hold while waiting for some other event to happen. An example is a router holding the packet while its ARP request is getting served. eBPF does not have the capability of holding the packet, thereby not allowing it to take ownership of the packet. A remedy suggested for this is the usage of a slow path module, executed in the userspace, that receives packets from the eBPF program and reacts consequently with respect to the processing defined by the developer. The necessity of such a slow path module is also highlighted in [9], wherein the authors use the OvS userspace module to process packets that do not match a flow in the OvS kernel eBPF data path.

e. **Flow sampling, monitoring:** Yunsong Lu implemented monitoring the whole virtual network stack from socket to virtual switch to physical NIC by making use of existing hooks which can be extended with eBPF and kprobes attached[10]. By the use of Canal View (a container networking framework from Huawei), which is the topology-based virtual networking monitoring system, monitoring of Application-to-Application network traffic was done. This was implemented by making use of NFV(Network Functions Virtualization), Cloud Native, IOVisor, and E2. IOVisor was used as the MDPC (Micro Data Plane Container) with the applications developed and deployed with a Docker-like mechanism. This resulted in a faster network data plane in the kernel.
Now, when it comes to the usage of eBPF in Kubernetes, the Cilium project [16] explains how existing products (Cilium, Weave Scope) leverage eBPF to work with Kubernetes. In specific, it describes what interactions with eBPF are interesting in the context of container deployment.

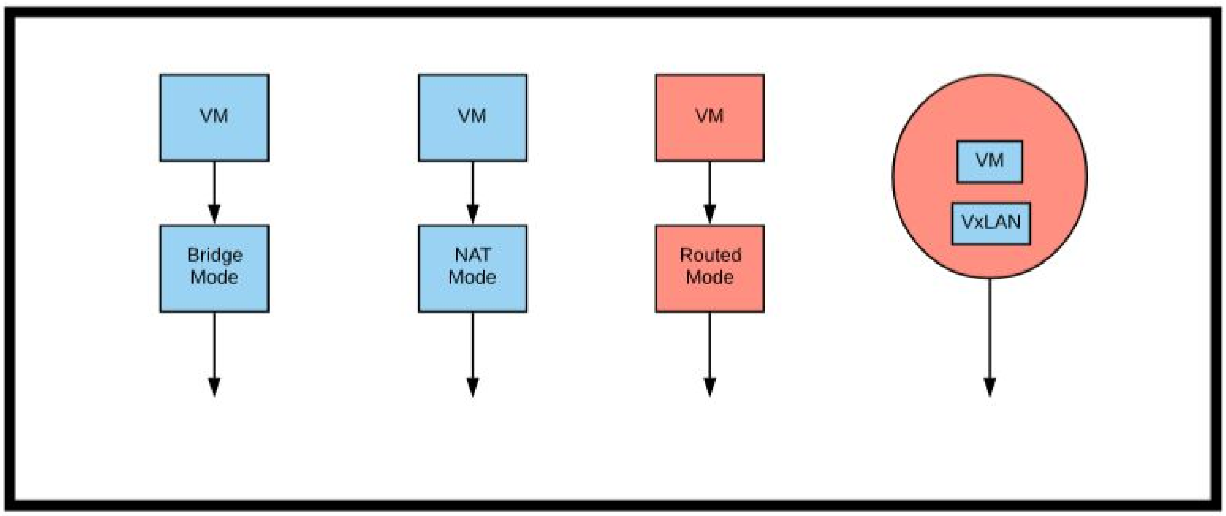
4. Functional specs

a. **Management Plane:** To be used as a **monitoring plugin** in a multi-tenant environment, the tenant provides the tenant ID to the plugin. The plugin-backend running on the hypervisor has information of tenant's network (bridges, network addresses). When the monitoring plugin starts, backend may receive information of other tenants as well at the tracepoints. The plugin-backend filters the only relevant tenant information and displays it on the front end.

b. **Firewall / Fast Data Path**: **Firewall:** The plugin front-end accepts Tenant ID and Firewall rules in form of IPtables commands. Plugin backend evaluates if the rule can be applied on the TC (Traffic Control) of hypervisor without affecting other tenants. If yes, plugin backend puts and eBPF byte code on the hypervisor. Else, it simply puts the iptables rules as is. **Fast Data Path:** The plugin takes packet from tenant VM's interface. Instead of letting the packet go through *_xmit() function of all the devices, eBPF changes the header of packets and device_id which bypasses all the networking devices to go to the *_xmit() of hypervisor interface.

1. Results

a) Monitoring



Base Scenario: Evaluating the time spent by packet in each device

We have considered four topologies (Bridge mode, NAT mode, Routed mode and VXLAN tunnel mode). We have taken 10 batches of readings with each batch comprising of 100 iterations, and the average is calculated for each batch. This is done for each of the aforementioned topologies.

Input: Ping from VM to 8.8.8.8. For VxLAN device, Ping was done to the VM in another namespace (having the destination TEP).

Results:
The timestamp seen in the snapshots are in nanoseconds.

- **Case I (Bridge Mode):**

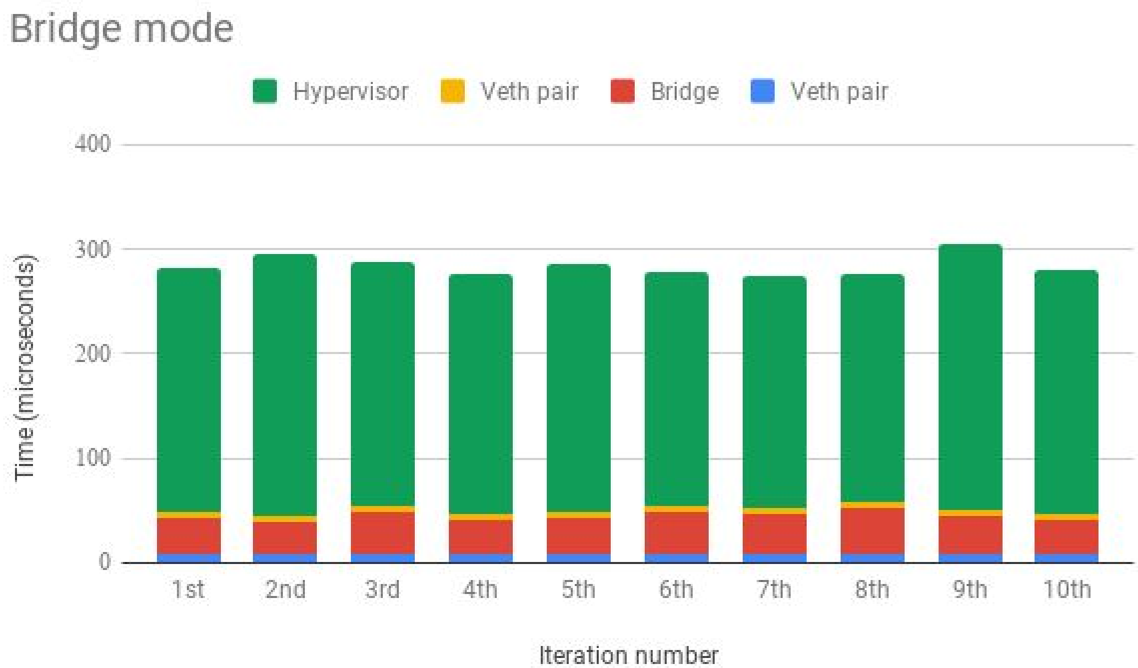
All times are in microseconds

Bridge mode



Maximum time is taken in the hypervisor. From our understanding, in addition to NATting, the hypervisor will even have to go through a much longer chain of iptables rules. In all the other cases too, maximum time is taken by the hypervisor.

Vxlan0 is the src and destination VxLAN device. Veth0 - veth1 is the link between Src VM namespace and router (which is a namespace). veth2 - veth3 is the link between router and destination VM namespace. 10.0.0.1 and 10.0.0.2 are VMs separated by namespace router. 192.168.100.1 and 192.168.200.1 are the tunnel-endpoint IPs.

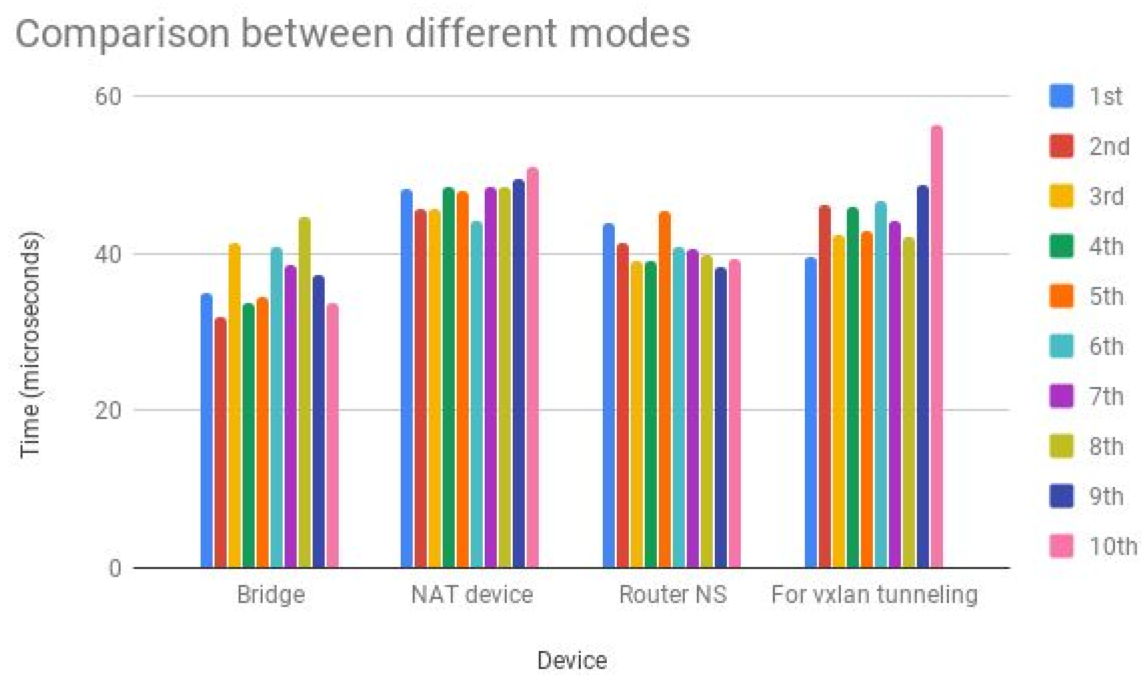
Screenshot of the last iteration of a batch



6. Future Work:

From our current topology we will use eBPF to evaluate the performance of network implementation of different Kubernetes CNI-plugins where we will measure the time spent by packet in OVS/linux bridges in different modes [Bridge (L2), Routed (L3), NAT, Tunnel]. We will also use eBPF with TC to Implement Fast Data Path/Firewall.
